

Conference Guide

4th PhD-Workshop on Polymer Reaction Engineering

30th October to 1st November 2015 in Fürstentfeldbruck

Welcome to the 4rd PhD-Student Workshop on Polymer Reaction Engineering

Dear company representatives, professors and PhD-students,

The PhD-Student Workshop on Polymer Reaction Engineering represents an international platform where young researchers in the field of polymer reaction engineering can build up valuable networks. It is an opportunity to meet fellow PhD-students and to get into contact with interesting companies and potential employers. Moreover, PhD-students can benefit from useful feedback on their work and improve their soft skills by practicing the presentation of complex scientific topics.

The workshop is being held for the forth time now and we would like to perpetuate it as an annual event. It has been launched in Lyon in 2012 with a total number of 35 participants. The second workshop has been organized in Hamburg in 2013 and involved 43 people. Last year it took place in San Sebastian with 37 attendees. This year we are recording a number 38 of registrations from universities as well as the industry.

Having participants from seven countries and various research fields we can look forward to an interesting and diverse workshop which contributions deal include the following topics:

- bulk, emulsion, miniemulsion, gas phase and high pressure polymerization
- structure-property relations regarding heat transfer, wettability and coagulation phenomena and extrusion as well as adhesion behavior
- homopolymers, copolymers, blends, foams, nanogels and hybridpolymers

- results obtained by new analytical methods

With all these topics ahead we are looking forward to an informative workshop in Fürstfeldbruck with you.

The Organizing Committee

Arrival in Fürstenfeldbruck: Public Transport & Your Way to the Workshop

Transfer from the Airport into Munich

From the airport you either take the train number S1 or S8 to the main station of Munich. This takes approximately 45 minutes.

From the main station you can get to the old city center by foot (ca. 15 min walk) or by taking a train (S1,2,3,4,6,7 or 8) from the main station to the stop Marienplatz.

Transfer from Munich to Fürstenfeldbruck

To get to Fürstenfeldbruck from the main station in Munich you can take train S4 in the direction of Grafrath. The train takes 26 mins for this route and runs approximately every 20 mins.

From the train station in Fürstenfeldbruck (1) it takes about 10 mins to walk to the Hotel Fürstfelder (2). From there it takes another 10 mins to get to the Veranstaltungsforum (Event Forum) Fürstenfeld (3), where the workshop is going to take place.

General Information

Language

The official language at the workshop is English.

Internet

You will be provided access to the WLAN in the Veranstaltungsforum Fürstenfeld when registering on Friday.

Insurance

The organizers do not accept responsibility for individual medical or personal insurance. Participants are strongly advised to take out their own insurance policies.

Telephone

The international code for Germany is +49.

Emergency phone numbers

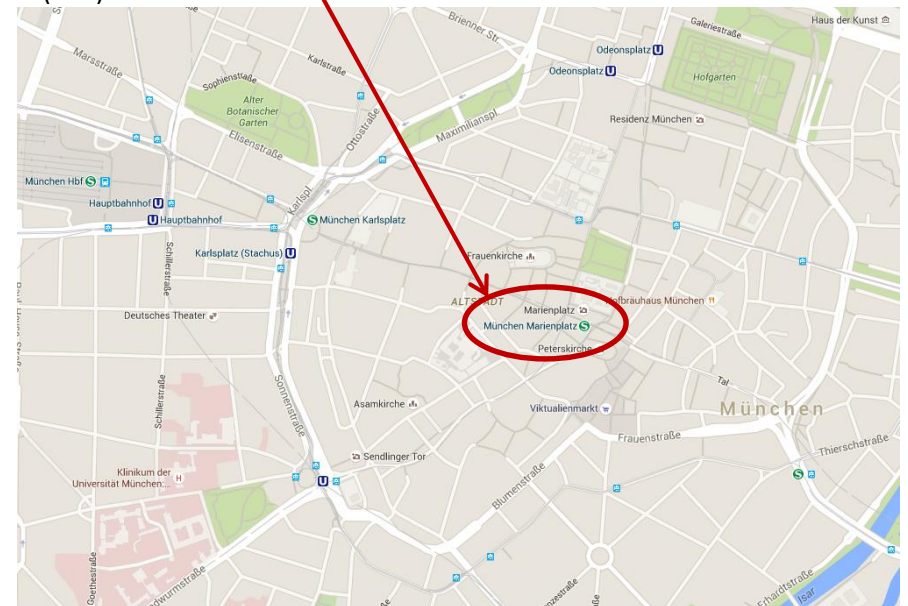

Police	110
Firebrigade	112
Ambulance	112

Programme by Days

Saturday, 31st October 2015

Session II: Modelling

Chair: Andra Nistor (University of Chemistry & Technology Prague)

- 08:50 - 09:10 **David Eckes** (Technical University Darmstadt)
Theoretical Evaluation of the Mechanical Degradation within an Industrial Multi-Zone LDPE Autoclave Reactor
- 09:10 - 09:30 **Esther Laryea** (Karlsruher Institute of Technology)
The Influence of Fluid Dynamics on the Kinetics of Free-Radical Polymerization
- 09:30 - 09:50 **Kristina Zentel** (Technical University Darmstadt)
Impact of Thermo-Physical Data on the Modelling of High Pressure Polymerizations
- 09:50 - 10:10 **Baldur Schroeter** (University Hamburg)
Spectroscopic Investigations on a Redox Initiator System for continuous Emulsion Polymerization
- 10:10 - 10:30 **Peter Fleckenstein** (ETH Zürich)
Modelling of the Ring Chain Equilibrium in Cyclic Oligomers of Polyethylene Furanoate (PEF)

10:30 - 11:10

Coffee Break and Poster Session

Session III: Emulsion Polymerization

Chair: Baldur Schroeter (University Hamburg)

- 11:10 - 11:30 **Kristina Rossow** (University Hamburg)
Tubular Reactor Concept for Process Intensification in Emulsion Polymerization
- 11:30 - 11:30 **Barthélémy Brunier** (LAGEP / CNRS-University of Lyon)
Analysis of the effect of Laponite® on Radical Exchange in Seeded Semibatch Pickering Emulsion Polymerization

Programme by Days

Saturday, 31st October 2015

Ring-opening polymerization (ROP) for high molecular weight polyethylene furanoate (PEF) synthesis and the analysis thereof using diffusion NMR (DOSY)

J.-G. Rosenboom, Giuseppe Storti, Massimo Morbidelli

ETH Zurich, Institute for Chemical and Bioengineering, Vladimir-Prelog-Weg 1, 8093 Zurich, Switzerland

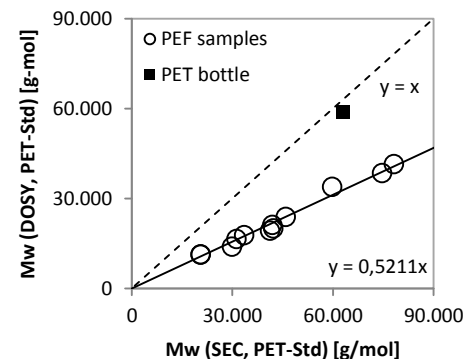

Along the shift of our societies from fossil-fuel based economies towards more sustainable civilizations, ring-opening polymerization (ROP) can be an alternative process to synthesize a novel class of renewable resource-based polymers. Furanic polyesters like polyethylene furanoate (PEF) have been ranked among the top potential chemicals by the US-DOE and may replace one of the world's dominant fossil-based plastics, polyethylene terephthalate (PET). Those alternative polymers have already been investigated and produced solely via polycondensation (PC) by a few research groups and companies such as Avantium incentivized by Coca-Cola [1-3]. ROP proceeds via living chain-growth mechanisms and thus may offer the advantages of better MW control, shorter reaction times and obsolete condensation product removal. As an alternative and facile method to measure MW of PEF we present diffusion NMR (DOSY) [4].

High molecular weight PEF via ROP. We produce high molecular weight (MW) PEF with a competitive process based on ring-opening polymerization (ROP). In contrast to PC, our ROP-based PEF synthesis does not require byproduct removal and thus reaction can be completed with conversions >95% after several minutes rather than days. Those fast reactions were performed in bulk at elevated temperatures above 270°C, which were high enough to melt or plasticize the cyclic monomers. Degradation of polymer and catalyst may occur after 15-30 minutes. However, reaction in solution at lower temperatures around 180°C have proven very slow and resulted in limited molecular weights. High molecular weights surpassing the requirements for plastic bottle blowing (60'000 g/mol, by SEC) have been produced in melt using several tin- and metal oxide catalysts. The coloring of PEF products, already reported in the literature, was found dependent on cyclic monomer purity and catalyst use. Lower reactivity or susceptibility to catalytic conversion could be assessed to the dimeric monomer species, while higher species were readily reacted. Maximum achievable molecular weight increased with general monomer purity. The higher glass temperature and lower melting point compared with PET allow for higher thermal stability and easier processing of the final bottles, respectively.

Molecular weight analysis with NMR DOSY.

While PEF is a polymer with promising characteristics, it challenges established MW analysis methods such as size exclusion chromatography (SEC), as it is only soluble in expensive solvents such as hexafluoro-2-propanol (HFIP) and requires special HFIP-resistant equipment.

In order to establish NMR DOSY as a facile method, we investigated the relevant parameters influencing diffusion and the NMR measurement itself. NMR DOSY applies pulsed field gradients to spatially label molecules and thus track their diffusive motion via size-dependent signal loss after magnetization refocussing. Using double stimulated echo pulse (dstegpd2) sequences for convection correction (CC) allowed very robust conduct of experiment in contrast to using simpler single stimulated echo sequences without CC. Sample concentration should be around 0.4 ± 0.1 mg/mL to balance the trade-off between good signal-to-noise and influence of concentration on viscosity and molecular crowding. A calibration using PET standards is readily established. A comparison of DOSY vs SEC results shows a clear linearity, while the observed offset of 50% underlines the different coiling behaviour of PEF in the applicable solvents. Molecular dynamics simulations on this topic are ongoing. NMR DOSY can compete with SEC on solvent use and measurement time. While adjusting diffusion times Δ to achieve full signal attenuation along the gradient strength curve is usually recommended, using a fixed average Δ for all standards and samples can save measurement time without significant loss of precision.

Impact of thermo-physical data on the modelling of high pressure polymerizations

K. Zentel, M. Busch

Technische Universität Darmstadt, Ernst-Berl-Institut, Darmstadt, Germany

Nowadays modelling is a basic instrument for process optimization. Especially for technologies, which are conducted under exceptional process conditions, such as high pressure polymerizations, simulations are a welcome alternative to costly experiments in miniplants.

The synthesis of Low Density Polyethylene (LDPE) is an example for such an industrial process, which is typically operated between 100°C and 300°C and under pressures up to 3000 bar. The mathematical prediction of process parameters for the LDPE-Synthesis, for instance conversion, molecular weight distribution and branching, has been studied and refined since the early 1970s. By now the process simulation for LDPE synthesis poses a crucial tool for the LDPE-process development and optimization. But for the conduction of reliable and precise process simulations it is essential to have a very profound knowledge and understanding of the process itself, its thermodynamics and kinetics and of course the structure-properties relationship of the resulting polymer. Therefore a uniform set of parameters is essential, which can describe the polymerization reaction independently of reactor type and process. However this proves to be a highly demanding task as numerous parameters have to be known sufficiently precise within a complex reaction network and under the extreme process conditions. This is why variable parameters are still necessary in the current simulation models in order to obtain good agreement between calculation and plant data [1]. For tube reactors these parameters are e.g. the initiator efficiency and the thickness of the fouling layer inside the reactor.

The existence of these variable parameters as well as systematic discrepancies within the reactor models give reason for further investigations. In order to identify and overcome the knowledge gaps a systematic sensitivity analysis of the existing model concerning possible faulty parameters is the reasonable approach. Firstly the fundamentals, such as the thermo-physical properties, which serve as the basis of the polymerization model, should be revisited. For the simulation these are the

- density
- heat capacity
- viscosity and
- heat transfer coefficient

of ethylene, LDPE and the reaction mixture.

These data have to be available in dependence on temperature, pressure and composition, respectively. For the calculation of the viscosity molecular weight and branching structure of the polymer can also be taken into account. Whereas the density, the heat capacity and the thermal conductivity primarily influence the heat balance of the model, the viscosity of the reaction mixture also influences the kinetics directly. Reaction steps that depend on polymer mobility, such as the termination reaction of the polymerization, exhibit a direct dependence on the viscosity even at low polymer concentrations.

The literature on these properties for the pure components under process conditions is scarcely available and mostly dates back to the 1950s and 60s. Furthermore it often contains extrapolations and was analyzed with outdated mathematical methods. Experimentally based data on mixture properties is virtually inexistent, thus ideal mixing rules are applied without questioning [2], [3]. Moreover it becomes evident that some of the authors obtain differing values for the thermo-physical properties at a given temperature and pressure. Thereby the discrepancies reach up to several percent.

In the next step the impact of these parameters on the process simulation of high pressure polymerizations was studied and evaluated by the example of an industrial tube reactor.

Effects could mainly be observed in the resulting temperature profile and the achieved conversion. However these effects were negligible for the heat transfer, but conspicuous for the heat capacity and striking for the viscosities. For the heat capacity a constant error was introduced and evaluated. For small errors the adjustment of the variable parameters makes it possible to diminish the deviation caused by the introduced error to a minimum. This proves the concept of the variable parameters and explains why they sometimes exhibit physically unrealistic values.

But LDPE also possesses special rheological properties due to its unique branching structure. Thus the correct prediction of the molecular mass distribution as well as the polymeric microstructure is of striking importance for this polymer as well. Therefore it is also interesting to examine whether the viscosity of the reaction mixture, which directly influences the polymerization kinetics, shows any influence on the calculated molecular mass distribution and polymeric microstructure.

Modeling of the ring chain equilibrium in cyclic oligomers of polyethylene furanoate (PEF)

Peter Fleckenstein, Giuseppe Storti and Massimo Morbidelli

ETH Zurich, Institute for Chemical and Bioengineering, Vladimir-Prelog-Weg 1, 8093 Zurich, Switzerland

The replacement of oil based chemicals by renewable resource based chemicals is one of the major issues chemical industry is facing right now. The alternative polymer polyethylene furanoate (PEF) is a possible substitute for polyethylene terephthalate (PET). It can be produced via ring-opening polymerization of cyclic oligoethylene furanoate (cyOEF). Several strategies can be used to produce these cyclic molecules from the two monomers furandicarboxylic acid (FDCA) and ethylene glycol (EG). We are exploring two promising routes which are depolymerization and reactive distillation, which are both techniques exploiting the ring chain equilibrium at high dilution. In both cases linear polymer chains of PEF are dissolved at high temperatures and reacted towards rings. This project is focused on the production of cyOEF using these techniques and the modeling of the ring-chain equilibrium of the cyOEF mixture.

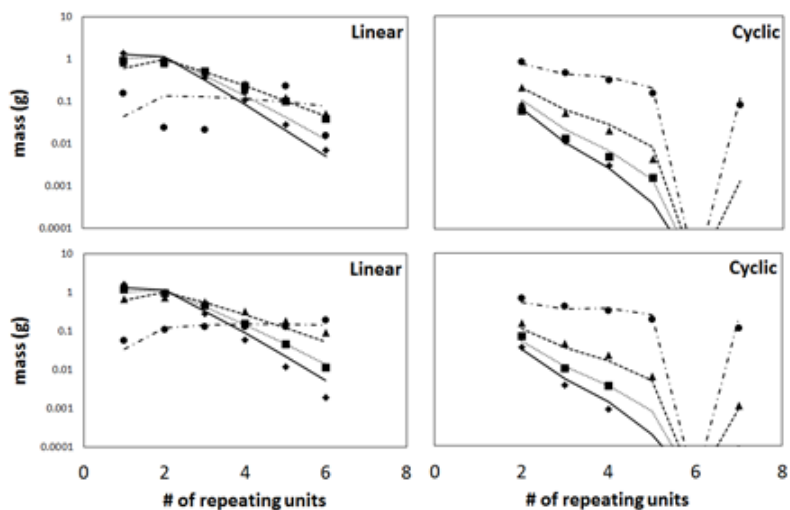

Figure 1. Comparison of experimental and model predicted cyclic and linear distributions at 2 different concentrations: 33 g/L (top) and 16 g/L (bottom). Data were taken at different molar ratios of EG to FDCA: 1:1 (●), 2:1 (▲), 3:1 (■) and 4:1 (◆).

Under high dilution, the equilibrium shifts towards the ring-chain formation of cyclic oligomers. The equilibrium model of Jacobson and Stockmayer (JS), derived in the 1950s, can be used to predict this equilibrium for several types of polymers. It is based on computing the probability of ring closure using the assumption of a randomly coiled hydrocarbon chains for linear polymers.

Two fitting parameters can be adjusted in this model. One is the equilibrium constant K for the step growth polymerization, which is in equilibrium with the cyclization reactions. The second one is b , the effective link length of the bonds in the polymer chains. The latter is usually independent on the repeating unit. Experimental results from depolymerization and reactive distillation were fitted using the JS model (Figure 1). A typical distribution of cyclic oligomers has a dominant peak for cyclic dimer and is decreasing for cyclic trimers, tetramers, pentamers and so on. Interestingly, the cyclic hexamer does not appear at all. Since in our case the experimental distributions did not match the JS theory perfectly, the model was extended introducing a link length for every individual cycle. Using this adjustment, the fitting to experimental data could be improved significantly. These results suggest that it is indeed possible to use the JS theory to describe the ring chain equilibrium also for PEF. The model should be further generalized and made capable of predicting the actual effective link length, which is currently a fitting parameter. Such further improvements should enable the model to predict also the absence of cyclics with 6 repeat units, which was experimentally observed and has not been physically explained in the literature so far.

Your notes:

Analysis of the effect of Laponite® on Radical exchange in seeded semibatch Pickering Emulsion Polymerization

Barthélémy Brunier, Yves Chevalier, Nida Sheibat-Othman, LAGEP / CNRS-University of Lyon, France

"Pickering" stabilization of latex particles has recently emerged as a new method to create nanocomposite colloids by adsorption of solid particles at solid latex interfaces [1] and is named "Emulsion polymerization" by analogy to solid-stabilized emulsions [2]. The elaboration of composite latexes allows combining attributes of inorganic solids with the processing and handling advantages of organic polymers which allows for instance to improve mechanical and water-resistance properties in waterborne organic coatings[3].

The stabilization of polymer latex particles elaborated by Pickering polymerization mainly takes place by steric repulsions between adsorbed inorganic solid particles. The later form a rigid mechanical barrier that prevents the polymer latexes from coalescing. Electrostatic phenomena do not significantly contribute to the colloidal stability. However, the presence of inorganic particles at the surface of polymer particles might affect radical adsorption and desorption due to their charges or to the mechanical barrier. Therefore the growth step during the polymerization may be affected by the presence of inorganic particles.

In this work, we investigate the effect of Laponite® clays concentration on radical exchange, and therefore particle growth, in emulsion polymerization of styrene, in the absence of surfactant or other additives. Both experimental and modelling investigations are handled.

Seeded experiments were realized by varying the amount of Laponite®. The used seed was produced at 70°C using potassium persulfate as initiator in presence of a small amount of Laponite® (for nucleation and stabilization). The seeded experiments start in interval III, eliminating therefore the nucleation phase. Experiments presenting coagulation were also eliminated, to ensure constant particle number. The focus can therefore be made on particle growth and more precisely radical entry (absorption) and exit (desorption) from the latex particles. Experimental estimation of the average number of radicals per particle demonstrates that radical exchange plays an important role in Pickering emulsion polymerization. However, the Laponite® concentration does not seem to affect the growth rate.

In parallel, the effect of Laponite® concentration on particle growth was investigated by modelling, which allows estimation of adsorption and desorption parameters that are not available in the literature.

Smith and Ewart [4] first described the transfer of free radical activity into the interior of a polymer particle by direct diffusion of a free radical into a polymer particle:

$$R_c^p = 4\pi \cdot r_p \cdot D_w [R^w] \cdot N_p = k_c^p \cdot [R^w] \cdot N_p$$

However, the diffusion theory only applies accurately to large uncharged particles. In order to apply this theory to smaller and charged particles, two additional phenomena must be considered: reversible absorption and electrostatic repulsion. For instance, free radical diffusion might be hindered due to the presence of anionic clay platelets on the surface of latex particles. With this modification, to be considered absorbed by the particles, a radical must propagate or terminate before eventual desorption. This is done by incorporating an efficiency absorption factor in the absorption equation (see Hansen and Ugelstad [5] [6] [7]). The net rate of radical absorption by a particle can be obtained from the following expression, accounting for the theory of mass transfer and the "absorption efficiency factor" F_p :

$$k_c^p = 4\pi \cdot r_p \cdot D_w \cdot \bar{F}_p$$

Hansen and Ugelstad [7] also proposed an equation that combines the electrostatic repulsion factor, with capture reversibility to obtain the expression of F_p . Using this model, the electrostatic repulsion factor was estimated with varying Laponite® concentration in a way to fit experimental data. This again confirms that the Laponite® concentration does not affect the growth rate.

Amorphous silica is among the most common, and widely investigated catalyst support in the polyolefins industry. In particular, metallocenes are supported on pure, or amorphous silica modified with different types of cocatalysts (e.g., methylaluminoxane (MAO), Triisobutyl aluminium (TIBA) etc.) or spacer groups (e.g., n-BuSnCl₃ etc.) to prepare supported catalysts which are then employed in industrial processes to produce different grades of polyolefins. The surface of untreated silica contains water, geminal, vicinal and isolated hydroxyl groups, collectively known as silanols. It is well known that the surface concentration and nature of silanol groups can be altered by the thermal and/or chemical treatment of the silica. However, it is difficult to establish the nature and concentration of the silanol groups at the silica surface that are most suitable for a specific metallocene for the generation of an active metallocenium cation and thus, for the optimal catalyst performance.

The objective of the present study is to investigate the effect of silica dehydroxylation temperature on the catalytic activity of Grace 948 silica supported (n-BuCp)₂ZrCl₂ metallocene in ethylene polymerization. Dehydroxylation temperatures considered are 200°C, 450°C and 600°C covering the commonly used temperatures range for silica supported metallocenes. Two synthesis methods have been used for supported catalysts: i) by grafting (n-BuCp)₂ZrCl₂ on silica modified by MAO and ii) by grafting (n-BuCp)₂ZrCl₂+MAO solution on silica. Furthermore, the polymerizations have been carried out both in slurry and gas phase processes by using two types of scavengers i.e., Triethyl aluminium (TEA) and Triisobutyl aluminium (TIBA). Finally, the influence of silica dehydroxylation temperature on molecular weight distribution (MWD) and crystallinity of the obtained polyethylene samples have been analyzed.

The obtained results show that for catalysts prepared with method 1, Aluminium content of the silica (dehydroxylated at different temperatures) after impregnation of MAO reduced with increasing the dehydroxylation temperature which can be attributed to decrease in Si-OH concentration. For catalysts prepared with method 2, Aluminium and Zirconium content of the catalysts remained almost constant. The intrinsic and average activity of silica supported (n-BuCp)₂ZrCl₂ in ethylene homo & copolymerizations was observed to increase with increasing silica dehydroxylation temperature from 200 to 600°C, both in slurry and gas phase processes (see Figure 1) for both types of catalyst synthesis methods. The same trend was also observed by using two different alkyl aluminiums (i.e., TEA and TIBA) as scavengers. However, MWD and crystallinity were found to remain unaffected by the silica dehydroxylation temperature.

Figure 1. Comparison of slurry phase homopolymerization kinetic profiles of catalysts prepared with different silica dehydroxylation temperature using method 1 and TIBA as scavenger.

A Novel Approach to Determine Partition Coefficients of Monomers in Polymer Dispersions via Headspace Gas Chromatography

*Eric J. Fischer, Giuseppe Storti, Massimo Morbidelli

Dispersion polymerization is a heterogeneous polymerization process carried out in the presence of a polymeric stabilizer within the reaction medium. Polymerization processes leading to the precipitation of polymer chains have been studied over the last five decades [1]. Dispersion polymerization – usually carried out in organic solvents – is especially useful to produce particles in the order of a few micrometers [2], closing the gap between emulsion and suspension polymerization [3]. Applications range from chromatography packing materials [4] to liquid crystal display spacers [5]. To model the reaction kinetics, many different aspects have to be considered: the contributions of the reaction loci (continuous and dispersed phase), the kinetics of the polymer build-up and the evolution of the particle size distribution. One of the most important aspects of such models is the accurate description of the interphase partitioning of the different reactants (with special emphasis on the concentration of the monomers in the polymer phase) as well as a thorough evaluation of the compatibility between the polymer and the selected reaction medium. The aim of this work is to assess the potentials of headspace gas chromatography (HSGC) as a fast and reliable technique to fully characterize the thermodynamic behavior of the polymer dispersion with a reasonable experimental effort and using small amounts of raw materials.

With reference to a two-phase system involving solvent- and polymer-rich phases, a step-by-step procedure has been developed to explore all partitioning aspects in the general multicomponent case (several monomers, two solvents).

As first step, the activity is determined for each two-component mixture of all the involved species. This is done by preparing a series of samples with changing molar composition, heating them up to the desired temperature, leaving them for equilibration and subsequently sampling the gas phase in equilibrium with the liquid phase. The areas of the relevant peaks obtained via GC (e.g. with a flame ionization detector (FID)) are divided by the areas obtained for the pure components. This ratio is defined as the activity of a two-phase mixture. A suitable thermodynamic model is used to correlate the activity and the liquid phase molar composition.

In a second step, a series of vials is prepared with a constant amount of dry polymer. To each of these vials, an increasing amount of the two-component solution with specific composition is added. These samples are also measured by HSGC and the activity is recorded. Using the thermodynamic model, the corresponding molar fraction of the two components is determined. As long as the sum of these two molar fractions is below 1, the liquid phase is non-existent.

On the other hand, the polymer phase is saturated and the first droplet of the liquid phase is formed at the moment where the sum reaches 1. This way, the amount of solution at the selected composition required to saturate the polymer phase is readily evaluated. This step is repeated with solutions at different composition while recording the amount of solution at saturation. Eventually, these amounts as well as their compositions can be plotted versus the liquid composition of the added solution: these data are used to evaluate the monomer/solvent partitioning between liquid and polymer phases again using suitable thermodynamic models. In the simplest case, partition coefficients can be used.

The procedure outlined above will be demonstrated with reference to specific systems typical of dispersion polymerization.
